# Physical and Metabolic Characteristics of Persons with Diabetes 

Catherine C. Cowie, PhD, M PH, and M aureen I. Harris, PhD, M PH

## SUMMARY

This chapter presents national and commu-nity-based data on physical and metabolic characteristics of persons with diabetes. The primary data sources are the 1989 National Health Interview Survey (NHIS), a household interview survey of a representative sample of persons age $\geq 18$ years; the 1976-80 Second National Health and Nutrition Examination Survey (NHANES II), which included a representative sample of the U.S. population age 20-74 years who were administered a household interview, a physical examination with certain clinical and laboratory tests, and an oral glucose tolerance test (OGTT) to detect undiagnosed diabetes; and the 1982-84 Hispanic Health and Nutrition Examination Survey (HHANES), which included Mexican Americans, Puerto Ricans, and Cuban Americans age 20-74 years from certain regions of the U.S. and employed methods similar to those used in the NHANES II.

By definition, persons with non-insulin-dependent diabetes mellitus (NIDDM) have much higher fasting plasma glucose levels (mean in undiagnosed NIDDM $=132 \mathrm{mg} / \mathrm{dl}$ ) than persons with impaired glucose tolerance (IGT) (mean $=98 \mathrm{mg} / \mathrm{dl}$ ) and persons with normal glucose tolerance (mean $=91 \mathrm{mg} / \mathrm{dl}$ ). Similar trends are found for 2-hour plasma glucose levels (means of 262,161 , and $97 \mathrm{mg} / \mathrm{dl}$, respectively). Self-reported frequency of urine glucose and high blood glucose in the past 6 months was reported more frequently in younger than in older persons and in NIDDM than in insulin-dependent diabetes mellitus (IDDM); fully $27 \%$ of persons with NIDDM age 18-44 years reported urine glucose or high blood glucose always or most of the time.

A family history of diabetes is more frequent in NIDDM than other groups. Based on NHANESII data among persons age 20-54 years, a parental history of
diabetes was reported in 46.6\% of those with a medical history of NIDDM, 24.7\% of persons with undiagnosed NIDDM, $30.1 \%$ of IGT, and $17.6 \%$ of persons with normal glucose tolerance; based on 1989 NHIS data, the percent was similar for adults with IDDM (16.4\%) and nondiabetic persons (17.3\%).

Mean body mass index (BMI) is highest in persons with NIDDM, followed by those with IGT, and persons with normal glucose tolerance. Among persons with NIDDM, the frequency of obesity ( $\mathrm{BMI} \geq 30$ ) is much higher in women (46.6\%) than in men (20.9\%), and is markedly high in non-Hispanic black women (69.5\%). Between 1976-80 and 1989, mean self-reported BMI increased in persons with NIDDM, particularly in non-Hispanic white women (26.9 to 28.6, a $6.3 \%$ increase). Central obesity is also more evident in persons with NIDDM and IGT compared with persons with normal glucose tolerance.

In general, mean blood pressure is as high in persons with undiagnosed NIDDM and IGT as in persons with a medical history of NIDDM, but lower in persons with normal glucose tolerance. Based on NHANES II data, the prevalence of hypertension ( $\geq 160 / 95 \mathrm{mmHg}$ or antihypertensive medication) in persons age 65-74 years is $\sim 60 \%$ in NIDDM, $50.7 \%$ in IGT, and 38.3\% in persons with normal glucose tolerance. Based on 1989 NHIS data, the prevalence of self-reported physiciandiagnosed hypertension in persons age 45-64 years is $63.7 \%$ in NIDDM and $25.4 \%$ in nondiabetic persons. The prevalence of self-reported hypertension in persons with previously diagnosed NIDDM was similar in 1976-80 and 1989. Among persons with NIDDM and self-reported physician-diagnosed hypertension, $76.3 \%$ said they were taking antihypertensive medication, $86.7 \%$ were restricting salt intake, $57.8 \%$ were engaging in physical exercise, and $70.2 \%$ were losing or controlling their weight.

Compared with nondiabetic persons, persons with NIDDM have higher mean total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides, and lower mean high-density lipoprotein (HDL) cholesterol. A high proportion of NIDDM patients have abnormal concentrations of lipoproteins. Among persons with NIDDM, the prevalence of total cholesterol $\geq 240 \mathrm{mg} / \mathrm{dl}$ is $37.4 \%$ in men and $43.7 \%$ in women; the respective rates in NIDDM men and women are 30.9\% and $43.8 \%$ for LDL cholesterol $\geq 160 \mathrm{mg} / \mathrm{dl}, 27.6 \%$ and $11.4 \%$ for HDL cholesterol $<35 \mathrm{mg} / \mathrm{dl}$, and $13.9 \%$ and $22.2 \%$ for fasting triglycerides $\geq 250 \mathrm{mg} / \mathrm{dl}$.

Parity is greater in persons with NIDDM than in non-
diabetic persons. Among women age $\geq 50$ years, $39.6 \%$ of NIDDM and $29.7 \%$ of nondiabetic persons have $\geq 4$ children. The frequency of babies $\geq 9 \mathrm{lbs}$. at birth is also higher in women with NIDDM. Except at youngest ages, a slightly higher percent of nondiabetic persons smoke (26.1\%) than do diabetic persons (20.1\%). Likewise, the percent drinking any al cohol is higher in nondiabetic ( $67.2 \%$ ) than in diabetic persons ( $46.6 \%$ ). Excellent or very good health status was reported in $64.9 \%$ of nondiabetic persons age $\geq 18$ years, but only in $19.5 \%$ of persons with NIDDM. The participation rate in leisure-time physical activity is lower in diabetic than in nondiabetic persons.

## INTRODUCTION

This chapter describes the physical and metabolic characteristics of persons with diabetes and is based primarily on three data sources. The first source is the 1989 NHIS, which is described in detail in Chapter 6. The second data source is the 1976-80 NHANES $I^{1}$, which included a sample of the general U.S. population age $20-74$ years ( $n=15,357$ ) that was representative of the United States by age, sex, race, geographic region, and level of income. Data from the NHANES II have provided national estimates of the prevalence of diabetes and IGT ${ }^{2,3}$. Household interviews were conducted to obtain demographic and medical history information, including whether subjects had a medical history of physician-diagnosed diabetes. Seventy-seven percent of the interviewed sample participated in a physical examination that included certain clinical and laboratory tests. Data on examined participants are similar to those from the 1976 NHIS (for which the $96 \%$ response rate approximates true population values) on $>70$ health-related variables ${ }^{2,4}$. Examined persons are also similar in distribution to the total U.S. population according to age, sex, race, income, and geographic region ${ }^{2}$. A representative half-sample of examined participants (excluding persons with previously diagnosed diabetes) were eligible for an OGTT. This test was administered according to recommendations of the National Diabetes Data Group (NDDG) ${ }^{5}$. Subjects fasted overnight for 10-16 hours; a fasting venous blood sample was taken; 75 g of glucose (Glucola, Miles/Ames) was ingested; and a venous blood sample was taken 2 hours later. Plasma glucose was measured using a microadaptation of the national glucose oxidase reference method ${ }^{6}$. The OGTT was completed by $66 \%$ of eligible subjects. Persons who received the OGTT
differed little or not at all from the total NHANES II interviewed sample without a medical history of diabetes with respect to age, sex, race, income, obesity, family history of diabetes, and a number of other demographic, clinical, and medical history factors ${ }^{2,3,7}$.

Using World Health Organization (WHO) criteria ${ }^{8}$, individuals who received the OGTT were classified by their plasma glucose values as having undiagnosed diabetes (fasting plasma glucose $\geq 140 \mathrm{mg} / \mathrm{dl}$ and/or 2 -hour glucose $\geq 200 \mathrm{mg} / \mathrm{dl}$; $\mathrm{n}=192$ ), IGT (fasting plasma glucose $<140 \mathrm{mg} / \mathrm{dl}$ and 2 -hour glucose 140 $199 \mathrm{mg} / \mathrm{dl} ; \mathrm{n}=532$ ), or normal glucose tolerance (fasting plasma glucose $<140 \mathrm{mg} / \mathrm{dl}$ and 2 -hour plasma glucose $<140 \mathrm{mg} / \mathrm{dl} ; \mathrm{n}=2,990$ ). Of 756 examined participants who reported a medical history of diabetes, 18 appeared to have IDDM based on age at diagnosis $<30$ years, continuous use of insulin since diagnosis, and BMI (weight in kg divided by height in m squared) $<27$ for men and $<25$ for women. These subjects were excluded from analysis. The remaining 738 subjects and all persons with diabetes detected by OGTT during the survey were considered to have NIDDM. Of the 738 subjects with a medical history of NIDDM, 544 subjects were examined. To provide estimates that are representative of the U.S. population, data were weighted by the inverse of the participation rate of study subjects according to age, sex, race, income, and region.

The third major data source is the HHANES, conducted in 1982-84. In this survey, people in three Hispanic groups were studied: Mexican Americans in the southwestern United States (California, Arizona, Colorado, New Mexico, and Texas; $n=3,928$ ), Puerto Ricans in the New York City area (New York, New Jersey, and Connecticut; $n=1,519$ ), and Cuban Americans in the Miami, FL area (Dade County; $n=1,134$ ). The HHANES used methods virtually identical to the

NHANES II, including a standard 75-g 2-hour OGTT given after an overnight 10-16 hour fast, according to NDDG recommendations. WHO criteria were used to classify persons as having undiagnosed diabetes (for all ethnic groups combined, $\mathrm{n}=70$ ), IGT ( $\mathrm{n}=192$ ), or normal glucose tolerance ( $n=1,042$ ). A medical history of diabetes was reported in an additional 423 individuals, of whom one person had probable IDDM; of the remaining 422 persons with a medical history of NIDDM, 356 persons were examined. Sampling weights were also applied to these data to provide estimates representative of the total Hispanic group of each region.

In addition to these national surveys, this chapter includes information provided by principal investigators of several community-based diabetes investigations. These include studies of diabetes in whites in Rancho Bernardo, CA ${ }^{10}$; Japanese Americans in Seattle, WA ${ }^{11}$; Hispanics and non-Hispanic whites in San Luis Valley, $\mathrm{CO}^{12}$ and San Antonio, $\mathrm{TX}^{13}$; and N ative Americans in Oklahoma, Arizona, N orth Dakota, and South Dakota ${ }^{14}$. (See Chapters 32, 33, and 34 for more detailed discussions of diabetes in these ethnic groups.)

## BLOOD GLUCOSE

Data on fasting and 2-hour post-challenge plasma glucose were not obtained for persons with diagnosed diabetes in the national surveys. However, this information was collected in several community-based studies on diabetes. Figures 7.1 and 7.2 show mean fasting and 2-hour post-challenge plasma glucose by race/ethnicity for women with previously diagnosed diabetes in community-based studies ${ }^{10-14}$. M ean fasting glucose is highest in Native American groups (212-242 mg/dl), followed by Hispanic groups in San Luis Valley, CO and San Antonio, TX (188-198 mg/dl). Mean fasting glucose is lowest in white women in Rancho Bernardo, CA ( $140 \mathrm{mg} / \mathrm{dl}$ ). For mean 2-hour plasma glucose in women, levels are highest in Pima Indians ( $356 \mathrm{mg} / \mathrm{dl}$ ), followed by Japanese Americans in Seattle, WA ( $336 \mathrm{mg} / \mathrm{dl}$ ), and Hispanics in San Luis Valley, CO and San Antonio, TX (332-334 mg/dl). Similar to fasting values, 2 -hour glucose is lowest in whites in Rancho Bernardo ( $219 \mathrm{mg} / \mathrm{dl}$ ). Data in men and data on plasma glucose levels in newly discovered diabetes in these community studies are presented below in the section titled "Comparison of $N$ ational and Community-Based Study Data."

Fasting plasma glucose values are shown by age in Figure 7.3 for persons age 20-74 years in the 1976-80

## Figure 7.1

Mean Fasting Plasma Glucose in Women with Previously Diagnosed NIDDM in C ommunity-Based Studies

See Appendices 7.46-7.48 for further details.
Source: References 10-14

NHANES II, excluding those with diagnosed diabetes for whom glucose values were not determined. At each age, mean plasma glucose and the values corresponding to the 10th, 50th (median), and 90th percentile of the entire distribution are shown. Mean fasting glucose for age 20-74 years combined is 90 $\mathrm{mg} / \mathrm{dl}$. Fasting glucose rises slightly with increasing age and is somewhat higher for those in the 90th percentile ( $100 \mathrm{mg} / \mathrm{dl}$ at age 20-44 years versus 112 $\mathrm{mg} / \mathrm{dl}$ at age 65-74 years). Two-hour post-challenge

Figure 7.2

Figure 7.3
Means and Percentiles of Fasting Plasma Glucose in Persons Without a Medical History of Diabetes, U.S., 1976-80

Individuals with a medical history of diabetes were not asked to fast and thus their plasma glucose could not be determined. Plasma glucose was measured in the morning after an overnight 10-16 hour fast. See Appendix 7.1 for further details.
Source: 1976-80 Second National Health and Nutrition Examination Survey
plasma glucose values are shown in Figure 7.4. For age 20-74 years combined, mean 2 -hour glucose is $109 \mathrm{mg} / \mathrm{dl}$. Two-hour glucose rises slightly with age, particularly for persons in the 90th percentile of the distribution ( $132 \mathrm{mg} / \mathrm{dl}$ at age 20-44 years versus 199 $\mathrm{mg} / \mathrm{dl}$ at age $65-74$ years). Detailed tables of plasma glucose values by race, sex, and age are found in Appendices 7.1 and 7.2. There are no striking trends by sex or race: fasting values are slightly higher in men than in women, but 2-hour values are slightly

Figure 7.4
Means and Percentiles of 2-Hour Plasma Glucose in Persons Without a Medical History of Diabetes, U.S., 1976-80

Individuals with a medical history of diabetes were not asked to fast and thus their plasma glucose could not be determined. Plasma glucose was measured at 2 hours after a $75-\mathrm{g}$ oral glucose challenge given in the morning after an overnight 10-16 hour fast. See Appendix 7.2 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
higher in women; Cuban Americans have somewhat higher values than the other race/ethnic groups.

Mean fasting plasma glucose is compared by diabetes status in Figure 7.5. By definition, persons with NIDDM have much higher fasting glucose levels than the other groups (overall mean in undiagnosed NIDDM $=132 \mathrm{mg} / \mathrm{dl}$ ), whereas levels in persons with IGT (mean $=98 \mathrm{mg} / \mathrm{dl}$ ) and normal glucose tolerance (mean $=91 \mathrm{mg} / \mathrm{dl}$ ) are similar. There is little difference by age. Trends by diabetes status for mean 2 -hour plasma glucose (Figure 7.6) are similar to those for fasting values except that 2 -hour glucose is more intermediate in persons with IGT (e.g., overall mean of 262, 161, and $97 \mathrm{mg} / \mathrm{dl}$ in undiagnosed NIDDM, IGT, and normal glucose tolerance, respectively). Mean fasting and 2 -hour glucose values are shown by diabetes status in further detail by sex and race in A ppendix 7.3. There are few differences by sex. The most substantial difference by race is found among persons with undiagnosed NIDDM, where levels are highest in Cuban Americans ( 141 and $280 \mathrm{mg} / \mathrm{dl}$ for fasting and 2 -hour values) and lowest in non-Hispanic blacks ( 128 and $253 \mathrm{mg} / \mathrm{dl}$ for fasting and 2 -hour values).

In the 1989 N HIS, diabetic persons age $\geq 18$ years were queried as to the frequency of urine glucose and high blood glucose during the previous 6 months. These data are shown in Figure 7.7. Both urine glucose and high blood glucose were reported less frequently in

Figure 7.5
Mean Fasting Plasma Glucose, by Diabetes Status,
U.S., 1976-80

[^1]Figure 7.6
Mean 2-Hour Plasma Glucose, by Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Individuals with a medical history of diabetes were not asked to fast and thus their plasma glucose could not be determined. Plasma glucose was measured at 2 hours after a $75-\mathrm{g}$ oral glucose challenge given in the morning after a 10-16 hour fast. Diabetes status was based on World Health Organization criteria'. See Appendix 7.3 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
persons with IDDM than with NIDDM ( $15.6 \%$ versus $22.1 \%$ for high blood glucose). The frequency decreased with older age. Fully $27 \%$ of persons with NIDDM age 18-44 years reported urine glucose or high blood glucose always or most of the time. Appendices 7.4 and 7.5 present these data in further detail.

Data from the 1989 NHIS on the presence of urine ketones in the past 6 months are shown in Appendix 7.6. The majority of persons stated that they were not
tested ( $48.5 \%$ of IDDM and $54.1 \%$ of NIDDM) or did not know if they were tested ( $8.1 \%$ of IDDM and $27.8 \%$ of NIDDM) for urine ketones.

## FAMILY HISTORY OF DIABETES

A history of diabetes in parents and siblings was ascertained in the 1976-80 NHANES II. Family history of diabetes is reported much more frequently in persons with a medical history of NIDDM than in all other groups (Figure 7.8). For example, at age 20-54 years, $46.6 \%$ of those with a medical history of diabetes report that they have a parent with diabetes, compared with $24.7 \%$ of those with undiagnosed NIDDM. The lower frequency in the latter group may contribute to the delay in diagnosis of NIDDM. Persons with IGT have a higher frequency of a family history of diabetes (e.g., $30.1 \%$ at age 20-54 years have a diabetic parent) than persons with normal glucose tolerance (17.6\%). Among those age 20-54 years with undiagnosed NIDDM, women report a parent having diabetes more frequently than men ( $36.0 \%$ versus $8.8 \%$ ), while men report a sibling having diabetes more frequently than women ( $22.3 \%$ versus 9.9\%) (Appendix 7.7). Clear patterns by race are not evident. A maternal history of diabetes generally was reported more frequently than a paternal history among persons with NIDDM (e.g., $21.4 \%$ versus $4.5 \%$ for undiagnosed NIDDM age $\geq 55$ years) and IGT ( $15.4 \%$ versus $3.3 \%$ at age $\geq 55$ years).

Parental history of diabetes was also ascertained in the 1989 NHIS. The proportion reporting a parental history of diabetes was of a similar order of magnitude for

Figure 7.7
Percent of Diabetic Persons Who Reported Having Urine Glucose or High Blood Glucose Always or Most of the Time During the Past 6 Months, U.S., 1989

[^2]Figure 7.8
Percent of Persons Age 20-74 Years with a Family History of Diabetes, by Age and Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a $75-\mathrm{g} 2$-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.7 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
persons with IDDM (16.4\% overall) and nondiabetic persons (17.3\%), and was much lower than the percent of NIDDM with a parental history (45.4\%) (Figure 7.9). Among those with NIDDM, a parental history of diabetes decreased slightly with age (52.4\% at age $18-44$ years versus $40.9 \%$ at age $\geq 65$ years). Persons with IDDM reported a paternal history of diabe-

Figure 7.9
Percent of Persons Age $\geq 18$ Years W ho Have a Diabetic Parent, by Age and Diabetes Status, U.S., 1989

[^3]tes more frequently than a maternal history (9.1\% versus 3.5\%), whereas persons with NIDDM more frequently reported a maternal history ( $24.7 \%$ versus 10.0\%) (Appendix 7.8). There were minimal differences by sex or race. Parental history of diabetes in persons with NIDDM is compared in communitybased studies in the section below titled "Comparison of $N$ ational and Community-Based Study Data."

## BODY MASS AND OBESITY

Figure 7.10 shows mean BMI calculated from measured height and weight for men and women based on the 1976-80 NHANES II. In both sexes, BMI is higher in persons with NIDDM than in persons with normal

Figure 7.10
Mean Body Mass Index in Men and Women, by Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.9 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
glucose tolerance and generally higher than that in persons with IGT. BMI is also higher in persons with IGT than in persons with normal glucose tolerance. For age 20-74 years, BMI is 28.1 in persons with a medical history of NIDDM, 29.5 in undiagnosed NIDDM, 27.4 in IGT, and 24.8 in persons with normal glucose tolerance. In most groups, BMI is higher in women than in men. Figure 7.11 shows mean measured BMI for persons with NIDDM according to race, based on the NHANES II and HHANES. Among those with a medical history of NIDDM, a higher BMI is found in non-Hispanic blacks (29.8), M exican Americans (30.2), and Puerto Ricans (29.3) than in nonHispanic whites (27.8) and Cuban Americans (26.4). Among persons with undiagnosed NIDDM, blacks have the highest mean BMI (31.9 versus 27.9-29.0). More detailed estimates of BMI are given in Appendix 7.9. Data on mean BMI in persons with NIDDM in community-based studies are presented in the section below titled "Comparison of N ational and Commu-nity-Based Study Data."

Figure 7.12 shows mean BMI according to sex and duration of diabetes in non-Hispanic whites. Except for men with undiagnosed diabetes, in whom BMI is low, BMI decreases with increasing duration of diabetes. The decline is not apparent in other racial/ethnic groups (Appendix 7.10).

The percent of persons with NIDDM who are obese,
Figure 7.11
Mean Body Mass Index in Persons Age 45-64 Years, by Race and Diabetes Status, U.S., 1976-80 and 1982-84

Diabetes status was determined by medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.9 for further details. NH, non-Hispanic.

Source: 1976-80 Second National Health and Nutrition Examination Survey
defined as having a $\mathrm{BMI} \geq 30$, is shown in Figure 7.13 by race and sex. The frequency of obesity is much higher in women (overall, 46.6\%) than in men (20.9\%) and is markedly high in non-Hispanic black women (69.5\%) and lowest in Cuban-American women (29.6\%). Among NIDDM men, the percent obese is highest in Mexican Americans (29.6\%) and Cuban Americans (28.3\%), and Iowest in Puerto Ricans (11.0\%). Appendix 7.11 shows more detailed estimates of obesity. In non-Hispanic whites, the per-

Figure 7.13
Percent of Persons with NIDDM Age 45-64 Years with Body Mass Index $\geq$ 30, by Sex and Race, U.S., 1976-80 and 1982-84

[^4]Source: 1976-80 Second National Health and Nutrition Examination Survey and 1982-84 Hispanic Health and Nutrition Examination Survey
cent with BMI $\geq 25$ increases slightly with age; however, the percent with BMI $\geq 30$ and $\geq 35$ decreases dramatically with age. In other race/ethnic groups, a pattern is less clear. Data on obesity in persons with NIDDM in community-based studies are presented in the section below titled "Comparison of N ational and Community-Based Study Data."

Mean measured and self-reported BMI are shown for persons with a medical history of NIDDM in Appendix 7.12 based on data from the 1976-80 NHANES II and the 1982-84 HHANES. Almost without exception, measured BMI is higher than self-reported BMI. At age 20-74 years, mean measured BMI is 28.1, 4.1\% higher than the self-reported BMI of 27.0. Women underreport BMI more than men ( 27.2 versus 26.6 in men and 28.7 versus 27.2 in women). Mexican Americans and Cuban Americans underreport BMI less than other race/ethnic groups, whereas non-Hispanic blacks underreport the most. Patterns by age are not particularly evident.

Self-reported BMI in persons with a medical history of NIDDM increased between 1976-80 and 1989 from 27.0 to 28.3, an increase of $4.8 \%$. The increase was found in non-Hispanic whites (26.7 to 28.1) and nonHispanic black women (28.9 to 30.0), but not in non-Hispanic black men or Mexican Americans in whom there was a decrease (Appendix 7.12). An increase in BMI was particularly evident in non-Hispanic white women (26.9 to 28.6, a 6.3\% increase). The increase in mean self-reported BMI in persons with NIDDM is similar to the increase in mean measured BMI for the general population age 20-74 years between 1976-80 (mean $\mathrm{BMI}=25.3$ ) and 1988-91 (mean $\mathrm{BMI}=26.3$ ), a $4 \%$ increase ${ }^{15}$. Overweight prevalence (defined as having a BMI of $\geq 27.8$ in men and $\geq 27.3$ in women) in the general population increased $8 \%$ during this period ${ }^{15}$.

## CENTRAL OBESITY

Subscapular-to-triceps skinfold ratio was available in the 1976-80 NHANES II and the 1982-84 HHANES as a measure of central obesity. This is shown according to sex, age, and diabetes status in Figure 7.14. A more central obesity is evident in persons with NIDDM and IGT, compared with persons with normal glucose tolerance. Appendix 7.13 provides more detailed estimates. For all adults, the ratio is substantially higher in men (1.47-1.70) than in women (0.82-1.02). A pattern by age is not apparent. Data on central obesity including waist-to-hip ratios in persons with NIDDM in community-based studies are presented in the sec-

Figure 7.14
Mean Subscapular-to-Triceps Skinfold Ratio in Men and Women, by Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.13 for further details.

tion below titled "Comparison of National and Com-munity-Based Study Data."

## BLOOD PRESSURE, HYPERTENSION, AND ANTIHYPERTENSIVE TREATMENT

In all age groups, for both systolic and diastolic blood pressures, mean blood pressure is higher in persons with NIDDM (both medical history and undiagnosed) and IGT than in persons with normal glucose tolerance (Figure 7.15). In general, mean blood pressure is as high in persons with undiagnosed NIDDM and IGT as in persons with a medical history of NIDDM. For

Figure 7.15
Mean Systolic and Diastolic Blood Pressure, by Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.14 for further details.
Source: 1976-80 Second National Health and Nutrition Examination Survey
example, at age 45-64 years, mean systolic blood pressure is 135 mmHg in persons with undiagnosed NIDDM, 136 mmHg in IGT, and 140 mmHg in persons with a medical history of NIDDM. Systolic blood pressure increases with age (e.g., 126 to 150 mmHg in medical history NIDDM age 20-44 years versus $\geq 65$ years). A difference by sex is most evident among persons with normal glucose tolerance, with women having lower blood pressure than men (e.g., systolic, 119 versus 126 mmHg ; diastolic, 76 versus 81 mmHg ) (Appendix 7.14). Both in persons with a medical history of NIDDM and undiagnosed NIDDM, mean blood pressure is highest in non-Hispanic blacks, followed by whites, compared with other race/ethnic groups (Figure 7.16); systolic blood pressure is 143 $\mathrm{mmHg}, 141 \mathrm{mmHg}$, and $129-132 \mathrm{mmHg}$ in these

Figure 7.16

groups, respectively. Data on mean blood pressures in persons with NIDDM in community-based studies are presented in the section below titled "Comparison of National and Community-Based Study Data."

Based on data from the N HAN ESII, trends by diabetes status in the prevalence of hypertension (defined using W HO criteria of $\geq 160 / 95 \mathrm{mmHg}$ or use of antihypertensive medication) are similar to trends for mean blood pressure. For example, among persons age 6574 years, prevalence of hypertension is 59.2\%-60.0\% in persons with NIDDM, $50.7 \%$ in persons with IGT, and $38.3 \%$ in persons with normal glucose tolerance (Figure 7.17). Prevalence increases with age in all

Figure 7.17
Percent with Hypertension, by Diabetes Status, U.S., 1976-80

IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. Hypertension is based on World Health Organization criteria, defined as a blood pressure of $\geq 160 / 95 \mathrm{mmHg}$ or use of antihypertensive medication. See Appendix 7.16 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
groups (e.g., among persons with a medical history of NIDDM , 27.3\% at age 20-44 years versus 60.0\% at age 65-74 years). Prevalence by race/ethnicity for persons with NIDDM is shown in Figure 7.18. Rates are higher in non-Hispanic whites and blacks than the three Hispanic groups, but Puerto Ricans at age 65-74 years have rates of hypertension as high as those in whites

Figure 7.18

NHW, non-Hispanic white; NHB, non-Hispanic black; MA, Mexican American. Data were obtained by self-response to questions about diabetes, self-response to a question about physician-diagnosed hypertension for persons with diabetes, and by self- or proxy response in a subsample of nondiabetic persons. See Appendix 7.17 for further details.
Source: 1989 National Health Interview Survey
and blacks (Appendix 7.15 ). Appendix 7.16 provides further details by race, sex, and age. Prevalence of hypertension is higher in women than in men with NIDDM, but lower in women than in men with IGT and those with normal glucose tolerance. Prevalence is highest in non-Hispanic blacks, followed by whites, among persons with NIDDM and normal glucose tolerance, and similarly high in these groups among persons with IGT. Data on the preval ence of hypertension in persons with NIDDM in community-based studies are presented in the section below titled "Comparison of N ational and Community-Based Study Data."

Self-reported prevalence of physician-diagnosed hypertension was obtained in the 1989 NHIS. As in the HANES, prevalence is substantially higher in persons with NIDDM than in nondiabetic persons (Figure 7.19). In those age 45-64 years, prevalence is $63.7 \%$ in NIDDM and $25.4 \%$ in nondiabetic persons. Hypertension prevalence rises with age (e.g., in NIDDM , 43.6\% at age 18-44 years versus $63.4 \%$ at age $\geq 65$ years) and is slightly higher in women (e.g., in NIDDM, 65.7\% versus $55.2 \%)$. Among persons with NIDDM, prevalence is highest in non-Hispanic blacks (71.3\%) and lowest in Mexican Americans (37.5\%). The prevalence of hypertension in persons with IDDM is much lower than in persons with NIDDM (overall, 19.4\% versus 61.3\%); among persons with IDDM, it increases with age but does not differ by sex (Appendix 7.17).

Figure 7.20
Percent with Hypertension in Persons with NIDDM Age 20-74 Years, U.S., 1976-80

Measured and self-reported prevalence of hypertension in 1976-80 and 1989 is shown in Appendix 7.18 for persons with previously diagnosed NIDDM. The prevalence of measured hypertension is lower than selfreported hypertension in 1976-80. Prevalence of self-reported hypertension was similar in 1976-80 and 1989.

Figure 7.20 classifies persons with NIDDM based on NHANES II and HHANES data in 1976-80 according to whether they report a history of physician-diagnosed hypertension and whether their blood pressure meets the W HO criteria for hypertension ( $\geq 160 / 95$ mmHg ) or the criteria for hypertension recommended by the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure ( $\geq 140 / 90$ $\mathrm{mmHg})^{16}$. Using the WHO criteria, $63 \%$ of persons with NIDDM have hypertension, about half (45\%) of which is uncontrolled. Using the Joint Committee criteria, $74 \%$ have hypertension, and about two-thirds of these are uncontrolled. Appendix 7.19 provides details on hypertension status by race and age.

In the 1989 NHIS, among persons with NIDDM age $\geq 18$ years who reported having physician-diagnosed hypertension, $76.3 \%$ said they were taking prescribed antihypertensive medication (Figure 7.21). In addition, $86.7 \%$ reported they were restricting salt intake, $57.8 \%$ said they were engaging in physical activity or exercise, and $70.2 \%$ reported they were losing weight or controlling their weight. Only $3.4 \%$ were doing none of these antihypertensive measures. Details are provided in Appendix 7.20. Use of antihypertensive medications increased with age (51.0\% at age 18-44

Figure 7.21
Percent of Persons with NIDDM Age $\geq 18$ Years with Self-Reported Physician-Diagnosed Hypertension W ho Use Antihypertensive Treatment, U.S., 1989

Physician-diagnosed hypertension and antihypertensive treatment were obtained by self-response.

Source: 1989 N ational Health Interview Survey
years versus $80.9 \%$ at age $\geq 75$ years), restriction of salt increased slightly in persons age $\geq 45$ years (about 87\%) compared with younger ages (76.3\%), whereas physical activity and weight loss or maintenance as an antihypertensive measure decreased with age (physical activity- $57.0 \%$ versus $48.2 \%$, weight loss- $68.5 \%$ versus $54.7 \%$ in ages $18-44$ years versus $\geq 75$ years, respectively). Differences by sex were not evident. M exican Americans were least likely to be using antihypertensive medications (63.8\%) and reportedly were most likely to be losing or maintaining their weight (81.4\%), compared with other race groups; non-Hispanic blacks were somewhat more likely to be restricting salt intake (91.1\%).

## SERUM LIPOPROTEINS

Mean values from NHANES II and HHANES for total cholesterol, LDL cholesterol, HDL cholesterol, and fasting triglycerides are presented in Appendices 7.217.28. At age $20-74$ years, mean total cholesterol concentration is higher in persons with NIDDM (232 $\mathrm{mg} / \mathrm{dl}$ ) and IGT ( $228 \mathrm{mg} / \mathrm{dl}$ ), compared with persons with normal glucose tolerance ( $208 \mathrm{mg} / \mathrm{dl}$ ); the difference is most striking in persons age 20-44 years (Appendices 7.21 and 7.25). Mean total cholesterol is higher in persons age 45-74 years ( $231-238 \mathrm{mg} / \mathrm{dl}$ ) than in younger ages (195-213 mg/dl) regardless of diabetes status, is higher in women with NIDDM (238 $\mathrm{mg} / \mathrm{dl})$ than in men with NIDDM ( $223 \mathrm{mg} / \mathrm{dl}$ ), and is
highest in non-Hispanic whites ( $236 \mathrm{mg} / \mathrm{dl}$ ) and Puerto Ricans ( $227 \mathrm{mg} / \mathrm{dl}$ ) with NIDDM compared with other race/ethnic groups (214-220 mg/dl).

Mean LDL cholesterol concentrations show similar trends as total cholesterol by diabetes status and age (Appendices 7.22 and 7.26). At age 20-74 years, mean LDL cholesterol is $151 \mathrm{mg} / \mathrm{dl}$ in NIDDM and 135 $\mathrm{mg} / \mathrm{dl}$ in persons with normal glucose tolerance. M ean LDL cholesterol is also higher in women with NIDDM ( $158 \mathrm{mg} / \mathrm{dl}$ ) than in men with NIDDM ( $141 \mathrm{mg} / \mathrm{dl}$ ) but is somewhat higher in men ( $139 \mathrm{mg} / \mathrm{dl}$ ) than women ( $131 \mathrm{mg} / \mathrm{dl}$ ) with normal glucose tolerance. Non-Hispanic whites and Puerto Ricans with NIDDM have higher mean LDL cholesterol (157-161 mg/dl) compared with other race/ethnic groups (125-140 $\mathrm{mg} / \mathrm{dl})$.

Mean HDL cholesterol concentration is somewhat lower in persons with NIDDM ( $46 \mathrm{mg} / \mathrm{dl}$ ), intermediate in persons with IGT ( $48 \mathrm{mg} / \mathrm{dl}$ ), and highest in persons with normal glucose tolerance ( $50 \mathrm{mg} / \mathrm{dl}$ ), regardless of age, sex, or race/ethnicity (Appendices 7.23 and 7.27). Mean HDL cholesterol increases slightly with age, is substantially higher in women ( $49-55 \mathrm{mg} / \mathrm{dl}$ ) than in men ( $42-45 \mathrm{mg} / \mathrm{dl}$ ), and is higher in non-Hispanic blacks (48-55 mg/dl) compared with other race/ethnic groups ( $41-50 \mathrm{mg} / \mathrm{dl}$ ).

Mean fasting triglyceride concentration is highest in persons with NIDDM ( $180 \mathrm{mg} / \mathrm{dl}$ ), intermediate in persons with IGT ( $156 \mathrm{mg} / \mathrm{dl}$ ), and lowest in persons with normal glucose tolerance ( $116 \mathrm{mg} / \mathrm{dl}$ ) (Appendices 7.24 and 7.28). M ean triglycerides tend to increase with age and are lower in non-Hispanic blacks than in other race/ethnic groups. Data on mean lipid concentrations in persons with NIDDM in community-based studies are presented in the section below titled "Comparison of N ational and Community-Based Study Data."

The prevalence of abnormal lipid concentrations for men and women age 20-74 years with NIDDM, based on the NHANESII, is shown in Figure 7.22. Abnormal concentrations are defined according to the $N$ ational Cholesterol Education Program (NCEP) ${ }^{18}$. Prevalence of total cholesterol $\geq 240 \mathrm{mg} / \mathrm{dl}$ is $37.4 \%$ for men with NIDDM and $43.7 \%$ for women; for the other three lipids, the respective rates in diabetic men and women are 30.9\% and 43.8\% for LDL cholesterol $\geq 160 \mathrm{mg} / \mathrm{dl}$, $27.6 \%$ and $11.4 \%$ for HDL cholesterol $<35 \mathrm{mg} / \mathrm{dl}$, and $13.9 \%$ and $22.2 \%$ for fasting triglycerides $\geq 250 \mathrm{mg} / \mathrm{dl}$. Detailed data on dyslipidemia by age, sex, race/ethnicity, and diabetes status are shown in Appendices 7.297.37. Data on abnormal concentrations of lipids in persons with NIDDM in community-based studies are

Figure 7.22
Percent with Abnormal Lipid C oncentrations ( $\mathrm{mg} / \mathrm{dl}$ ) in Persons with NIDDM Age 20-74 Years, U.S., 1976-80

LDL cholesterol is estimated by: total cholesterol - HDL cholesterol - fasting triglycerides/5 for subjects whose triglycerides were $<400 \mathrm{mg} / \mathrm{dl}^{17}$. Individuals with a medical history of NIDDM were not asked to fast; thus their fasting triglyceride and LDL cholesterol levels could not be determined. See Appendices 7.33 and 7.35-37 for further details.

Source: 1976-80 Second National Health and Nutrition Examination Survey
presented in the section below titled "Comparison of National and Community-Based Study Data."

## PARITY

Parity is contrasted by age, sex, and diabetes status in Figure 7.23 based on the 1989 NHIS. Persons with

Figure 7.23
Percent of Persons with $\geq 4$ Children, by Age (Years), Sex, and Diabetes Status, U.S., 1989

Diabetes status was determined by self-response. See Appendix 7.39 for further details.

Source: 1989 National Health Interview Survey

NIDDM report a higher frequency of $\geq 4$ children than nondiabetic persons in every age and sex group. For example, in women age $\geq 50$ years, $39.6 \%$ of NIDDM and $29.7 \%$ of nondiabetic persons have $\geq 4$ children. Women with NIDDM report a higher frequency of $\geq 4$ children than men ( $36.6 \%$ versus $17.9 \%$ at age $\geq 18$ years). In both men and women with NIDDM, a higher percent of Mexican Americans report having $\geq 4$ children (50.0\%-67.8\%), followed by non-Hispanic blacks (43.3\%-49.1\%) and whites (28.9\%-34.3\%) (Appendix 7.38). Further detail is given in Appendix 7.39.

Appendix 7.40 presents data on parity among women from the 1976-80 NHANES II. In these data, parity was also higher in women with NIDDM than in nondiabetic women, the mean number of children being 3.3 in women with a medical history of NIDDM, 3.6 in undiagnosed NIDDM, and 2.2 in women with normal glucose tolerance. Among non-Hispanic whites, the mean number of children was higher in women with IGT (2.8) than in women with normal glucose tolerance (2.2). The mean number of children was the same in 1976-80 and 1989 (Appendices 7.39-7.40) in women with a medical history of NIDDM (3.3) but decreased slightly in 1989 in nondiabetic women (2.2 to 2.0). Women with a medical history of NIDDM reported a higher mean number of babies $\geq 9$ pounds at birth (0.8), followed by women with undiagnosed NIDDM (0.5), and by women with normal glucose tolerance (0.3). Among non-Hispanic whites, the mean number of babies $\geq 9 \mathrm{lbs}$. at birth was higher in IGT (0.4) than in women with normal glucose tolerance (0.3).

## SMOKING

Except at age 18-44 years, a slightly higher percent of nondiabetic persons currently smoke than do diabetic persons (overall, $20.1 \%$ versus $26.1 \%$ ) (Figure 7.24). The percent who smoke decreases with age (e.g., in persons with diabetes, $32.1 \%$ at age 18-44 years versus $12.3 \%$ at age $\geq 65$ years) and is higher in men than in women (e.g., in diabetic persons, $23.6 \%$ versus $17.6 \%)$. Detailed data by age, sex, and race are presented in Appendix 7.41. The higher rate in men than in women is particularly prominent among non-Hispanic blacks with diabetes ( $34.5 \%$ versus $15.4 \%$ ). Prevalence of smoking is similar by race. Among persons age 18-49 years, the prevalence of smoking is higher in NIDDM than IDDM, particularly among men (38.4\% versus 29.2\%) (Appendix 7.42).

Figure 7.24
Percent of Persons Age $\geq 18$ Years W ho Smoke, by Diabetes Status, U.S., 1989

Diabetes status was determined by self-response. See A ppendix 7.41 for further details.
Source: 1989 N ational Health Interview Survey

## ALCOHOL

Self-reported information on alcohol intake was obtained in the 1976-80 NHANES II and 1982-84 HHANES. The percent drinking any alcohol was higher in nondiabetic ( $67.2 \%$ overall) than diabetic persons (46.6\%), regardless of age, sex, or race (Appendix 7.43). The percent drinking alcohol decreased with age, particularly in nondiabetic persons (e.g., $72.3 \%$ at age $20-44$ years versus $52.0 \%$ at age 65-74 years), was higher in men than in women (e.g., in diabetic persons, $63.8 \%$ versus $34.7 \%$ ), and was somewhat lower in Mexican Americans compared with non-Hispanic whites and blacks (e.g., in diabetic persons, $36.0 \%$ versus $46.2 \%$ versus $38.9 \%$, respectively).

## HEALTH STATUS

Participants in the 1989 NHIS provided a self-assessment regarding overall health status when queried by interview; these data are shown in Figure 7.25 and Appendix 7.44 according to diabetes status. A substantially lower percent of persons with NIDDM reported excellent or very good health status compared with nondiabetic persons. At age $\geq 18$ years, whereas 64.9\% of nondiabetic persons reported excellent or very good health status, only $19.5 \%$ of persons with NIDDM reported this. Among persons with IDDM, 38.7\% considered themselves in excellent or very good health. Excellent or very good health status

## Figure 7.25

Percent of Persons Age $\geq \mathbf{1 8}$ Years Who Report Excellent or Very Good Health, by Diabetes Status, U.S., 1989

Diabetes status was determined by self-response. NHW, non-Hispanic white; NHB, non-Hispanic black; MA, Mexican American. See Appendix 7.44 for further details.

Source: 1989 National Health Interview Survey
declined with age (e.g., in NIDDM, 29.4\% at age 18-44 years versus $18.2 \%$ at age $\geq 65$ years), was higher in men than in women (e.g., in NIDDM, $23.3 \%$ versus $16.7 \%$ ), and was higher in non-Hispanic whites (21.3\% in NIDDM) than in blacks ( $15.0 \%$ in NIDDM) and Mexican Americans (12.6\% in NIDDM).

## PHYSICAL ACTIVITY

A special questionnaire on Health Promotion and Disease Prevention was administered to participants of the 1990 NHIS. The questionnaire was used to obtain information on self-reported leisure-time physical activity patterns in a representative sample of the U.S. population ${ }^{19}$. Persons with diabetes were less likely to have participated in physical activity than nondiabetic persons, particularly in regular exercise (Appendix 7.45). For example, the participation rate in regular exercise was significantly lower in diabetic than in nondiabetic persons at age $\geq 45$ years ( 28.8 versus 35.5 at age $45-64$ years, 26.1 versus 33.1 at age $\geq 65$ years), among women ( 28.1 versus 38.2), and among whites ( 35.2 versus 41.8).

COMPARISON OF NATIONAL AND COMMUNITY-BASED STUDY DATA

Various physical and metabolic characteristics of persons with NIDDM in national and community-based data are compared in Appendices $7.46-7.48$. Mean fasting and 2 -hour plasma glucose in persons with previously diagnosed diabetes have been described in the section titled "Blood Glucose." Among previously diagnosed persons with diabetes, mean fasting insulin is highest in white men in Rancho Bernardo, CA ( 35 $\mu \mathrm{u} / \mathrm{ml}$ ) and lowest in Japanese-American men in Seattle, WA ( $15.0 \mu \mathrm{u} / \mathrm{ml}$ ). Except for whites in Rancho Bernardo, mean 2 -hour insulin levels in persons with previously diagnosed diabetes are consistently higher in women ( $73.6-116.7 \mu \mathrm{u} / \mathrm{ml}$ ) than in men (49.2-87.6 $\mu \mathrm{u} / \mathrm{ml}$ ). Duration of diabetes is longest in Native Americans in Arizona (13-14 years).

Among persons newly discovered to have diabetes by an OGTT, no trends by race/ethnicity or sex in mean fasting and 2 -hour plasma glucose are evident. Mean fasting insulin tends to be highest in Native American groups. M ean 2-hour insulin data were unavailable for Native Americans but were highest in Japanese Americans compared with the other race/ethnic groups.

A parental history of diabetes in persons with NIDDM is reported much more frequently in Japanese Americans ( $57.1 \%-81.8 \%$ ), Arizona Native Americans ( $62.3 \%-63.1 \%$ ), and Oklahoma Native American women ( $61.7 \%$ ), compared with other race/ethnic groups ( $20.2 \%-52.2 \%$ ). Data on family history were unavailable in Mexican Americans in the HHANES and in San Antonio, TX.

Except among Japanese Americans and whites in Rancho Bernardo, CA, mean BMI among persons with NIDDM is higher in women (30.4-33.7) than in men (26.9-32.7), and is highest in $N$ ative Americans (30.733.7) compared with other race/ethnic groups (24.832.1). Figure 7.26, which shows the percent of women with NIDDM who have BMI $\geq 30$, concurs with the trends by race/ethnicity and sex: fully $60 \%-71 \%$ of Native American groups have this level of obesity. In addition, $65.4 \%$ of black women have this level of obesity. Among women, the percent obese is lowest in Japanese Americans (18.2\%) and whites in Rancho Bernardo (19.0\%). Except among whites in Rancho Bernardo, the percent with BMI $\geq 30$ is higher in women than in men. Based on subscapular-to-triceps skinfold and waist-to-hip ratios, a more central obesity is evident in men than in women except in Native American groups (Appendices 7.46-7.48).

Figure 7.26
Percent with BMI $\geq \mathbf{3 0}$ in Women with NIDDM in U.S. and Community-Based Studies

Source: 1976-80 Second National Health and Nutrition Examination Survey, 1982-84 Hispanic Health and Nutrition Examination Survey, and References 10-14

Mean blood pressure tends to be higher in men than in women with NIDDM, especially diastolic blood pressure (Appendices 7.46-7.48). M ean systolic blood pressure is highest in whites in Rancho Bernardo, CA (142-146 mmHg) and lowest in Dakota Indians (122.8-127.5 mmHg), whereas diastolic blood pressure is highest in blacks (88.9-89.0 mmHg) and lowest in Mexican Americans and Anglos in San Antonio, TX (71.9-77.6 mmHg). The prevalence of hypertension in NIDDM, defined as blood pressure $\geq 160 / 95$ $\mathrm{mmH} g$ or use of antihypertensive medication, is highest in black women (71.2\%) and Anglo women in San Luis Valley, CO (71.4\%) (Figure 7.27). Prevalence is lowest in black men (29.5\%), in Mexican Americans in HHANES (22.8\%-25.0\%) and San Antonio (22.3\%25.8\%), and in the Dakota Indians (24.2\%-25.6\%).

Mean total cholesterol concentrations are higher in women with NIDDM (184.1-246.9 mg/dl) than in men (181.1-226.9 mg/dl) (Appendices 7.46-7.48). Mean total cholesterol is highest in white women in NHANES II ( $246.9 \mathrm{mg} / \mathrm{dl}$ ), in Rancho Bernardo, CA ( $235 \mathrm{mg} / \mathrm{dl}$ ), and in Hispanic women in San Luis Valley, CO ( $244.3 \mathrm{mg} / \mathrm{dl}$ ); it is lowest in Arizona (181.1-184.1 mg/dl) and Oklahoma (190.7-197.2 $\mathrm{mg} / \mathrm{dl})$ N ative Americans. A trend by sex in mean LDL cholesterol concentration is not evident. M ean LDL cholesterol is highest in white women in the 1976-80 NHANES II (162.4 mg/dl) and lowest in Native Americans ( $100.4-118.7 \mathrm{mg} / \mathrm{dl}$ ), particularly in Arizona ( $100.4-105.6 \mathrm{mg} / \mathrm{dl})$. Women with NIDDM have higher mean HDL cholesterol concentrations (43.6-

Figure 7.27
Percent with Hypertension in Women with NIDDM in U.S. and Community-Based Studies

Hypertension is based on World Health Organization criteria, defined as a blood pressure of $\geq 160 / 95 \mathrm{mmHg}$ or use of antihypertensive medication. See Appendices 7.46-7.48 for further details.
Source: 1976-80 Second National Health and Nutrition Examination Survey, 1982-84 Hispanic Health and Nutrition Examination Survey, and References 10-14
$63 \mathrm{mg} / \mathrm{dl}$ ) than do men ( $37.8-55.4 \mathrm{mg} / \mathrm{dl}$ ). Mean HDL cholesterol is particularly high in Japanese-American women ( $60.6 \mathrm{mg} / \mathrm{dl}$ ) and in white women in Rancho Bernardo ( $63 \mathrm{mg} / \mathrm{dl}$ ); mean concentrations are much more similar in all other race/ethnicity and sex groups. Mean fasting triglyceride concentrations are highest in Hispanic women in San Luis Valley (268.9 $\mathrm{mg} / \mathrm{dl}$ ) and in Anglo men in San Antonio, TX (276.6 $\mathrm{mg} / \mathrm{dl}$ ) and lowest in Japanese-American women ( $125.1 \mathrm{mg} / \mathrm{dl}$ ) and black men ( $131 \mathrm{mg} / \mathrm{dl}$ ); no trend by sex is evident.

Appendices 7.46-7.48 also provide information on the percent of persons with NIDDM having abnormal serum lipoprotein concentrations based on NCEP criteria ${ }^{18}$. These data for women are illustrated in Figure 7.28 and Appendices 7.49-7.51. The percent with total cholesterol $\geq 240 \mathrm{mg} / \mathrm{dl}$ and LDL cholesterol $\geq 160$ $\mathrm{mg} / \mathrm{dl}$ is higher in women than men (total: 10.7\%51.2\% versus 5.4\%-44.3\%; LDL: 5.9\%-49.9\% versus $2.8 \%-34.3 \%$ ), whereas the percent with HDL cholesterol $<35 \mathrm{mg} / \mathrm{dl}$ is higher in men than women ( $16 \%$ $53.1 \%$ versus $0 \%-25.7 \%$ ); the percent with fasting triglycerides $\geq 250 \mathrm{mg} / \mathrm{dl}$ is not consistently different by sex. Among women with NIDDM , the percent with abnormal concentrations of total cholesterol (Figure 7.28 ) is highest both in whites in NHANES II (51.2\%) and in Rancho Bernardo, CA (45\%) and lowest in $N$ ative American groups (5.4\%-16.9\%). The percent of women with abnormal concentrations of LDL cholesterol (Appendix 7.49) is also different by race/eth-

Figure 7.28
Percent with Total Cholesterol $\geq \mathbf{2 4 0} \mathbf{~ m g} / \mathrm{dl}$ in Women with NIDDM in U.S. and Community-Based Studies

Source: 1976-80 Second National Health and Nutrition Examination Survey, 1982-84 Hispanic Health and Nutrition Examination Survey, and References 10-14
nicity, being highest in NHANES II whites (49.9\%) and lowest in Native Americans (2.8\%-9.6\%). Among women, Anglos in San Luis Valley, CO are most likely to have abnormal HDL cholesterol concentrations (25.7\%) (Appendix 7.50). However, this is not replicated in whites in other studies; indeed, the percent of women with abnormal HDL concentration is lowest among whites in Rancho Bernardo (1\%) and among Japanese Americans (0\%). The percent of women with abnormal triglyceride concentrations (Appendix 7.51 ) is highest in Anglos in San Luis Valley (37.1\%) and lowest in Japanese Americans (4.5\%) and Mexican Americans in HHANES (6.7\%). Similar trends by race/ethnicity in abnormal lipid concentrations are found for men (Appendices 7.46-7.48).

Dr. Catherine C. Cowie is Senior Epidemiologist, Social and Scientific Systems, Bethesda, M D, and Dr. M aureen I. Harris is Director, National Diabetes Data Group, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD.

| IGT, impaired glucose tolerance. Fasting values are measured in the morning after an overnight 10-16 hour fast. Values at 2 hours are measured after a 75-g oral glucose challenge. Diabetes status is based on World Health Organization criteria. |  |  |  |  |  |  |
|  |  |  |  |  |  |  |

Appendix 7.4
Percent of Diabetic Persons Age $\geq 18$ Years Who Report Having U rine Glucose in Past 6 Months, U.S., 1989

| Race, sex, age (years), <br> and type of diabetes | Always/most of the time | Sometimes | Rarely/never | Not tested/don't know |
| :--- | :---: | :---: | :---: | :---: |
| IDDM | 14.2 | 26.3 | 13.7 | 45.9 |
| $18-39$ | 17.4 | 24.1 | 12.9 | 45.6 |
| $\geq 40$ | 3.6 | 33.5 | 16.3 | 46.6 |
| Men | 14.0 | 26.7 | 11.8 | 47.6 |
| Women | 14.4 | 15.9 | 43.7 |  |
| NIDDM | 17.7 | 19.7 | 26.4 | 36.2 |
| 18-44 | 27.1 | 18.5 | 22.2 | 32.3 |
| $45-64$ | 20.3 | 18.1 | 25.6 | 36.0 |
| 265 | 13.3 | 21.4 | 37.2 |  |
| Men | 19.5 | 19.7 | 34.9 |  |
| Women | 16.5 | 17.0 | 26.9 | 37.0 |
| Non-Hispanic whites | 16.8 | 26.3 | 39.9 |  |
| Non-Hispanic blacks | 17.7 | 20.9 | 31.2 | 25.0 |
| Mexican Americans | 23.5 |  | 22.1 | 33.5 |

Data are self-reported and based on self-testing and testing by physicians or others. Not tested/don't know includes persons who were not tested, persons who did not know whether they were tested, and persons who were tested but did not know the test results.

| Cuban Americans | 140 | 146 | 134 |
| Puerto Ricans | 161 | 140 | 125 |

IGT, impaired glucose tolerance; LDL, low-density lipoprotein; HDL, high-density lipoprotein. Diabetes status was determined by results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria. LDL cholesterol is estimated by: total cholesterol - HDL cholesterol - fasting triglycerides $/ 5$ for subjects whose triglycerides were $<400 \mathrm{mg} / \mathrm{dl}^{1}$. Individuals with a medical history of NIDDM were not asked to fast; thus their fasting triglyceride and LDL cholesterol levels could not be determined.

Percent of Persons Age 20-74 Years with HDL
C holesterol < $35 \mathrm{mg} / \mathrm{dl}$, by Age, Sex, Race, and Diabetes Status, U.S., 1976-80 and 1982-84

HDL, high-density lipoprotein; IGT, impaired glucose tolerance. Diabetes status was determined by medical history and results of a $75-\mathrm{g} 2$-hour oral glucose tolerance test using World Health Organization criteria. See Appendix 7.36 for further details.

Appendix 7.32
Percent of Persons Age 20-74 Years with Fasting Triglycerides $\geq \mathbf{2 5 0} \mathbf{~ m g} / \mathrm{dl}$, by Age, Sex, Race, and Diabetes Status, U.S., 1976-80 and 1982-84

IGT, impaired glucose tolerance. Diabetes status was determined by results of a 75 -g 2-hour oral glucose tolerance test using World Health Organization criteria. Individuals with a medical history of NIDDM were not asked to fast; thus their fasting triglyceride levels could not be determined. See Appendix 7.37 for further details.

## Appendix 7.35

## Percent of Persons Age 20-74 Years with LDL C holesterol $\geq 160 \mathrm{mg} / \mathrm{dl}$, by Diabetes Status, U.S., 1976-80 and 1982-84

| Race, sex, and <br> age (years) | Undiagnosed <br> NIDDM | IGT | Normal |
| :--- | :---: | :---: | :---: |
| All ages | 38.5 | 33.4 | 25.3 |
| $20-44$ | 21.2 | 27.6 | 16.7 |
| $45-64$ | 43.8 | 33.6 | 39.7 |
| $65-74$ | 39.4 | 40.0 | 42.5 |
| Men | 30.9 | 31.6 | 27.6 |
| Women | 43.8 | 34.6 | 23.0 |
| Non-Hispanic whites | 45.1 | 32.3 | 25.9 |
| Non-Hispanic blacks | 13.3 | 42.4 | 21.2 |
| Mexican Americans | 19.1 | 16.5 | 13.7 |
| Cuban Americans | 30.9 | 38.3 | 21.1 |
| Puerto Ricans | 27.0 | 25.5 | 16.6 |

IGT, impaired glucose tolerance; LDL, low-density lipoprotein; HDL, highdensity lipoprotein. Diabetes status was determined by results of a $75-\mathrm{g} 2$-hour oral glucose tolerance test using World Health Organization criteria. LDL cholesterol is estimated by: total cholesterol - HDL cholesterol - fasting triglycerides/5 for subjects whose triglycerides were $<400 \mathrm{mg} / \mathrm{dl}{ }^{17}$ Individuals with a medical history of NIDDM were not asked to fast; thus their fasting triglyceride and LDL cholesterol levels could not be determined.

| Previously diagnosed diabetes |  |  |  |  |  |  |
| M ean fasting plasma glucose (mg/dl) | 221.1 | 242.6 | 197.4 | 211.9 | 210.9 | 225.4 |
| Mean 2-hour plasma glucose (mg/dl) | 341.9 | 356.1 | 298.6 | 247.4 | 297.1 | 275.8 |
| M ean fasting insulin ( $\mu \mathrm{u} / \mathrm{ml}$ ) | 23.5 | 29.7 | 24.1 | 29.4 | 21.6 | 26.5 |
| Mean number of years since diagnosis of diabetes | 13.0 | 14.0 | 9.0 | 10.8 | 7.9 | 9.0 |
| Newly discovered diabetes |  |  |  |  |  |  |
| M ean fasting plasma glucose ( $\mathrm{mg} / \mathrm{dl}$ ) | 154.0 | 164.7 | 168.5 | 156.2 | 149.7 | 149.5 |
| M ean 2-hour plasma glucose (mg/dl) | 257.1 | 287.8 | 254.9 | 256.2 | 256.0 | 262.5 |
| M ean fasting insulin ( $\mu \mathrm{u} / \mathrm{ml}$ ) | 30.0 | 32.3 | 29.0 | 29.6 | 26.5 | 27.2 |
| All diabetic subjects combined |  |  |  |  |  |  |
| Percent with self-reported history of diabetes in mother and/or father | 62.3 | 63.1 | 47.0 | 61.7 | 52.2 | 48.9 |
| M ean BMI | 31.2 | 33.4 | 32.7 | 33.7 | 30.7 | 31.9 |
| Percent with BMI $\geq 25$ | 85.2 | 89.1 | 93.4 | 94.5 | 90.0 | 90.6 |
| Percent with BMI $\geq 30$ | 48.4 | 66.1 | 64.7 | 71.0 | 56.3 | 60.6 |
| Percent with BMI $\geq 35$ | 20.1 | 35.8 | 28.7 | 40.3 | 12.5 | 26.0 |
| M ean waist-to-hip ratio | 0.97 | 0.96 | 0.98 | 0.94 | 1.01 | 0.96 |
| Mean systolic blood pressure ( mmHg ) | 131.2 | 131.0 | 134.8 | 130.0 | 127.5 | 122.8 |
| M ean diastolic blood pressure ( mmHg ) | 81.6 | 76.6 | 83.3 | 76.9 | 80.3 | 74.8 |
| Percent with hypertension | 39.4 | 32.4 | 41.9 | 41.2 | 25.6 | 24.2 |
| M ean total cholesterol ( $\mathrm{mg} / \mathrm{dl}$ ) | 181.1 | 184.1 | 190.7 | 197.2 | 203.9 | 203.9 |
| M ean LDL cholesterol ( $\mathrm{mg} / \mathrm{dl}$ ) | 100.4 | 105.6 | 115.5 | 115.5 | 118.2 | 118.7 |
| M ean HDL cholesterol ( $\mathrm{mg} / \mathrm{dl}$ ) | 43.0 | 43.7 | 38.9 | 44.4 | 37.8 | 43.6 |
| M ean fasting triglycerides ( $\mathrm{mg} / \mathrm{dl}$ ) | 190.5 | 173.5 | 179.9 | 179.4 | 224.7 | 197.6 |
| Percent with total cholesterol $\geq 240 \mathrm{mg} / \mathrm{dl}$ | 6.7 | 10.7 | 5.4 | 12.2 | 16.9 | 15.0 |
| Percent with LDL cholesterol $\geq 160 \mathrm{mg} / \mathrm{dl}$ | 2.8 | 5.9 | 9.6 | 7.1 | 8.1 | 9.1 |
| Percent with HDL cholesterol $<35 \mathrm{mg} / \mathrm{dl}$ | 29.3 | 20.7 | 39.5 | 16.4 | 34.4 | 21.7 |
| Percent with triglycerides $\geq 250 \mathrm{mg} / \mathrm{dl}$ | 16.6 | 15.7 | 18.0 | 16.8 | 23.1 | 21.5 |

BMI, body mass index; LDL, low-density lipoprotein; HDL, high-density lipoprotein. Hypertension defined as systolic blood pressure $\geq 160 \mathrm{mmHg}$ or diastolic blood pressure $\geq 95 \mathrm{mmHg}$ or using antihypertensive medication; values for blood pressure includes values for subjects using antihypertensive medications. American Indian tribes are: Arizona- Pima, Maricopa; Oklahoma-The Seven Tribes (Apache, Caddo, Comanche, Delaware, Fort Sill Apache, Kiowa, Wichita); North Dakota/South Dakota-Oglala Sioux, Cheyenne River Sioux, Devil's Lake Sioux.

[^8]Appendix 7.49
Percent with LDL C holesterol $\geq \mathbf{1 6 0} \mathbf{~ m g} / \mathrm{dl}$ in Women with NIDDM in U.S. and Community-Based Studies

LDL, Iow-density lipoprotein. See Appendices 7.46-7.48 for further details.
Source: 1976-80 Second National Health and Nutrition Examination Survey, 1982-84 Hispanic Health and Nutrition Examination Survey, and References 10-14

Appendix 7.50
Percent with HDL Cholesterol < $35 \mathrm{mg} / \mathrm{dl}$ in Women with NIDDM in U.S. and C ommunity-Based Studies

HDL, high-density lipoprotein. See Appendices 7.46-7.48 for further details. Rate in Japanese American women in Seattle, WA was 0\%.

[^0]:    See Appendices 7.46-7.48 for further details.

[^1]:    IGT, impaired glucose tolerance. Individuals with a medical history of diabetes were not asked to fast and thus their plasma glucose could not be determined. Plasma glucose was measured in the morning after an overnight 10-16 hour fast. Diabetes status was determined by results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria ${ }^{8}$. See Appendix 7.3 for further details.

[^4]:    See Appendix 7.11 for further details. NH, non-Hispanic.

[^5]:    Diabetes status was determined from medical history and results of a 75-g 2-hour oral glucose tolerance test using World Health Organization criteria.
    Source: 1976-80 Second National Health and Nutrition Examination Survey and 1982-84 Hispanic Health and Nutrition Examination Survey

[^6]:    LDL, Iow-density lipoprotein; IGT, impaired glucose tolerance. Diabetes status was determined by results of a $75-\mathrm{g} 2$-hour oral glucose tolerancetest using World Health Organization criteria. LDL cholesterol is estimated by: total cholesterol HDL cholesterol - fasting triglycerides/5 for subjects whose triglycerides were $<400 \mathrm{mg} / \mathrm{dd} .{ }^{17}$ Individuals with a medical history of NIDDM werenot asked to fast; thus their fasting triglyceride and LDL cholesterol levels could not be determined. See Appendix 7.26 for further details.
